TODAY'S AGENDA

Processing Models

Access Methods

Modification Queries

Expression Evaluation

PROCESSING MODEL

A DBMS's **processing model** defines how the system executes a query plan and moves data from one operator to the next.
→ Different trade-offs for workloads (OLTP vs. OLAP).

Each processing model is comprised of two types of execution paths:
→ **Control Flow**: How the DBMS invokes an operator.
→ **Data Flow**: How an operator sends its results.

The output of an operator can be either whole tuples (NSM) or subsets of columns (DSM).

PROCESSING MODEL

Approach #1: Iterator Model ← *Most Common*

Approach #2: Materialization Model ← *Rare*

Approach #3: Vectorized / Batch Model ← *Common*

ITERATOR MODEL

Each query plan **<u>operator</u>** implements a `Next()` function.
→ On each invocation, the operator returns either a single tuple or a EOF marker if there are no more tuples.
→ The operator implements a loop that calls `Next()` on its children to retrieve their tuples and then process them.

Each operator implementation also has `Open()` and `Close()` functions.
→ Analogous to constructors/destructors, but for operators.

Also called **<u>Volcano</u>** or **<u>Pipeline</u>** Model.

ITERATOR MODEL

The Iterator model is used in almost every DBMS.
→ Easy to implement / debug.
→ Output control works easily with this approach.

Allows for **pipelining** where the DBMS tries to process each tuple through as many operators as possible before retrieving the next tuple.

MATERIALIZATION MODEL

Each operator processes its input all at once and then emits its output all at once.
→ The operator "materializes" its output as a single result.
→ The DBMS can push down hints (e.g., `LIMIT`) to avoid scanning too many tuples.
→ Can send either a materialized row or a single column.

The output can be either whole tuples (NSM) or subsets of columns (DSM).
→ Originally developed by MonetDB in the 1990s to process entire columns at a time instead of single tuples.

MATERIALIZATION MODEL

Better for OLTP workloads because queries only access a small number of tuples at a time.
→ Lower execution / coordination overhead.
→ Fewer function calls.

Not ideal for OLAP queries with large intermediate results because DBMS must allocate buffers.

与 ITERATOR MODEL 的区别： Next() 函数返回 a single tuple or all tuples.

VECTORIZATION MODEL

Like the Iterator Model where each operator implements a `Next()` function, but…

Each operator emits a **batch** of tuples instead of a single tuple.
→ The operator's internal loop processes multiple tuples at a time.
→ The size of the batch can vary based on hardware or query properties.
→ Each batch will contain one or more columns each their own null bitmaps.

VECTORIZATION MODEL

R   **S**
VECTORIZATION MODEL

Ideal for OLAP queries because it greatly reduces the number of invocations per operator.

Allows an out-of-order CPU to efficiently execute operators over batches of tuples.
→ Operators perform work in tight for-loops over arrays, which compilers know how to optimize / vectorize.
→ No data or control dependencies.
→ Hot instruction cache.

VECTORIZATION MODEL

→ Operators perform work in tight for-loops over arrays, which compilers know how to optimize / vectorize.
→ No data or control dependencies.
→ Hot instruction cache.

OBSERVATION

In the previous examples, the DBMS starts executing a query by invoking **Next()** at the root of the query plan and *pulling* data up from leaf operators.

This is the how most DBMSs implement their execution engine.

PLAN PROCESSING DIRECTION

Approach #1: Top-to-Bottom (Pull)
→ Start with the root and "pull" data up from its children.
→ Tuples are always passed between operators using function calls (unless it's a pipeline breaker).

Approach #2: Bottom-to-Top (Push)
→ Start with leaf nodes and "push" data to their parents.
→ Can "fuse" operators together within a for-loop to minimize intermediate result staging. operator fusion

PLAN PROCESSING DIRECTION

Approach #1: Top-to-Bottom (Pull) ← *Most Common*
→ Easy to control output via `LIMIT`.
→ Parent operator blocks until its child returns with a tuple.
→ Additional overhead because operators' `Next()` functions are implemented as <mark>virtual functions</mark>.
→ Branching costs on each `Next()` invocation.

Approach #2: Bottom-to-Top (Push) ← *Rare*
→ Allows for tighter control of <mark>caches/registers</mark> in pipelines.
→ May not have exact control of intermediate result sizes.
→ Difficult to implement some operators (Sort-Merge Join).

ACCESS METHODS

An **access method** is the way that the DBMS accesses the data stored in a table.
→ Not defined in relational algebra.

Three basic approaches:
→ Sequential Scan.
→ Index Scan (many variants).
→ Multi-Index Scan.

```
SELECT R.id, S.cdate
  FROM R JOIN S
    ON R.id = S.id
 WHERE S.value > 100
```
SEQUENTIAL SCAN

For each page in the table:
→ Retrieve it from the buffer pool.
→ Iterate over each tuple and check whether to include it.

```
for page in table.pages:
  for t in page.tuples:
    if evalPred(t):
      // Do Something!
```

The DBMS maintains an internal cursor that tracks the last page / slot it examined.

SEQUENTIAL SCAN OPTIMIZATIONS

Lecture #14 Task Parallelization / Multi-threading

Lecture #08 Clustering / Sorting

Lecture #12 Late Materialization

Materialized Views / Result Caching

Data Skipping

Lecture #14 Data Parallelization / Vectorization

Code Specialization / Compilation

DATA SKIPPING

Approach #1: Approximate Queries (Lossy)
→ Execute queries on a <mark>sampled subset</mark> of the entire table to produce approximate results.
→ **Examples**: BlinkDB, Redshift, ComputeDB, XDB, Oracle, Snowflake, Google BigQuery, DataBricks

Approach #2: Zone Maps (Lossless)
→ Pre-compute columnar aggregations per page that allow the DBMS to check whether queries need to access it.
→ Trade-off between page size vs. filter efficacy.
→ **Examples**: Oracle, Vertica, SingleStore, Netezza, Snowflake, Google BigQuery

ZONE MAPS

Pre-computed aggregates for the attribute values in a page. DBMS checks the zone map first to decide whether it wants to access the page. 预先计算页中属性值的聚合信息

```
SELECT * FROM table
WHERE val > 600
```

Parquet

Apache ORC

```
SELECT * FROM table
 WHERE val > 600
```

Parquet

Apache **ORC**

INDEX SCAN

The DBMS picks an index to find the tuples that the query needs.

Lecture #15

Which index to use depends on:
→ What attributes the index contains
→ What attributes the query references
→ The attribute's value domains
→ Predicate composition
→ Whether the index has unique or non-unique keys

INDEX SCAN

Suppose that we have a single table with 100 tuples and two indexes:
→ Index #1: **age**
→ Index #2: **dept**

```
SELECT * FROM students
  WHERE age < 30
    AND dept = 'CS'
    AND country = 'US'
```

Scenario #1

There are 99 people under the age of 30 but only 2 people in the CS department.

Scenario #2

There are 99 people in the CS department but only 2 people under the age of 30.

MULTI-INDEX SCAN

If there are multiple indexes that the DBMS can use for a query:
→ Compute sets of Record IDs using each matching index.
→ Combine these sets based on the query's predicates (union vs. intersect).
→ Retrieve the records and apply any remaining predicates.

Examples:
→ DB2 Multi-Index Scan
→ PostgreSQL Bitmap Scan
→ MySQL Index Merge

PG 内存中使用 bitmap 数据结构对所有 tuple-pointers 进行排序，通过提高对表数据的局部性引用来优化数据的访问性能。

MULTI-INDEX SCAN

```
SELECT * FROM students
 WHERE age < 30
   AND dept = 'CS'
   AND country = 'US'
```

Given the following query on a database with an index #1 on **age** and an index #2 on **dept**:
→ We can retrieve the Record IDs satisfying **age<30** using index #1.
→ Then retrieve the Record IDs satisfying **dept='CS'** using index #2.
→ Take their <mark>intersection</mark>.　多个索引求交集
→ Retrieve records and check **country='US'**.

MULTI-INDEX SCAN

Set intersection can be done efficiently with bitmaps or hash tables.

```
SELECT * FROM students
 WHERE age < 30
    AND dept = 'CS'
    AND country = 'US'
```

age<30

dept='CS'

record ids

record ids

fetch records

country='US'
MODIFICATION QUERIES

Operators that modify the database (**INSERT**, **UPDATE**, **DELETE**) are responsible for modifying the target table and its indexes.
→ Constraint checks can either happen immediately inside of operator or deferred until later in query/transaction.

The output of these operators can either be Record Ids or tuple data (i.e., **RETURNING**).

MODIFICATION QUERIES

UPDATE/DELETE:
→ Child operators pass Record IDs for target tuples.
→ Must keep track of previously seen tuples.

INSERT:
→ **Choice #1**: Materialize tuples inside of the operator.
→ **Choice #2**: Operator inserts any tuple passed in from child operators. select into

UPDATE QUERY PROBLEM

Control Flow ➡
Data Flow ➡

```
CREATE INDEX idx_salary
    ON people (salary);
```
```
for t in child.Next():
    removeFromIndex(idx_salary, t.salary, t)
    updateTuple(t.salary = t.salary + 100)
    insertIntoIndex(idx_salary, t.salary, t)
```

更新索引信息

```
UPDATE people
    SET salary = salary + 100
 WHERE salary < 1100
```

```
for t in Index_people:
    if t.salary < 1100:
        emit(t)
```

Index(people.salary)

Index(people.salary)

HALLOWEEN PROBLEM

Anomaly where an update operation changes the physical location of a tuple, which causes a scan operator to visit the tuple multiple times.
→ Can occur on clustered tables or index scans.

First discovered by IBM researchers while working on System R on Halloween day in 1976.

**Solution**: Track modified record ids per query.

EXPRESSION EVALUATION

The DBMS represents a **WHERE** clause as an **expression tree**.

The nodes in the tree represent different expression types:
→ Comparisons (**=**, **<**, **>**, **!=**)
→ Conjunction (**AND**), Disjunction (**OR**)
→ Arithmetic Operators (**+**, **−**, *****, **/**, **%**)
→ Constant Values
→ Tuple Attribute References
→ Functions

```
SELECT R.id, S.cdate
  FROM R JOIN S
    ON R.id = S.id
 WHERE S.value > 100;
```

EXPRESSION EVALUATION

```
PREPARE xxx AS
 SELECT * FROM S
  WHERE S.val = $1 + 9
```

```
EXECUTE xxx(991)
```

Execution Context

| Current Tuple (123, 1000) | Query Parameters (int:991) | Table Schema S→(int:id, int:val) |

➡ [=]

Attribute(S.val)   [+]

Parameter($1)   Constant(9)

EXPRESSION EVALUATION

          Parameter($1)    Constant(9)
              991              9
```
EXPRESSION EVALUATION

Evaluating predicates by traversing a tree is terrible for the CPU.
→ The DBMS traverses the tree and for each node that it visits, it must figure out what the operator needs to do.

A better approach is to evaluate the expression directly.

An even better approach is to **vectorize** it evaluate a batch of tuples at the same time…

```
SELECT * WHERE s.val = 1;
```

=

Attribute(s.val)   Constant(1)

```
bool check(val) {
    return (val == 1);
}
```
gcc, Clang, LLVM, …

Machine Code

EXPRESSION EVALUATION: OPTIMIZATIONS

`WHERE UPPER(col1) = UPPER('wutang');`

Constant Folding:

→ Identify redundant / unnecessary operations that are wasteful.

→ Compute a sub-expression on a constant value once and reuse result per tuple.
EXPRESSION EVALUATION: OPTIMIZATIONS

```
WHERE UPPER(col1) = UPPER('wutang');
```

Constant Folding:

```

CONCLUSION

The same query plan can be executed in multiple different ways.

(Most) DBMSs will want to use index scans as much as possible.

Expression trees are flexible but slow.
JIT compilation can (sometimes) speed them up.
